## Abstract

This paper presents the R package **GAS** for the analysis of time series under the Generalized Autoregressive Score (GAS) framework of Creal *et al.* (2013) and Harvey (2013). The distinctive feature of the GAS approach is the use of the score function as the driver of time–variation in the parameters of nonlinear models. The **GAS** package provides functions to simulate univariate and multivariate GAS processes, estimate the GAS parameters and to make time series forecasts. We illustrate the use of the **GAS** package with a detailed case study on estimating the time–varying conditional densities of a set of financial assets.

Keywords: GAS, time series models, score models, dynamic conditional score, R software.

## 1. Introduction

Time-variation in the parameters describing a stochastic time series process is pervasive in almost all applied scientific fields. Early references to time series models include Kalman (1960) and Box and Jenkins (1970). In many settings, the model of interest is characterized by time-varying parameters, for which the literature has proposed a myriad of possible specifications. Recently, Creal et al. (2013) and Harvey (2013) note that many of the proposed models are either difficult to estimate (in particular, the class of stochastic volatility models reviewed in Shephard (2005)) and/or do not properly take the shape of the conditional distribution of the data into account. Creal et al. (2013) and Harvey (2013) therefore propose to use the score of the conditional density function as the main driver of time-variation in the parameters of the time series process used to describe the data. A further advantage of using the conditional score as driver is that the estimation by Maximum Likelihood is straightforward. The resulting model is referred to as: Score-Driven model, Dynamic Conditional Score (DCS) model, or Generalized Autoregressive Score (GAS) model. In this article and accompanying R package, we use the GAS acronym for both.

The R package **GAS** is conceived to be of relevance for the modelling of all types of time series data. It does not matter whether they are real-valued, integer-valued, (0,1)-bounded or strictly positive, as long as there is a conditional density for which the score function and the Hessian are well-defined. The practical relevance of the GAS framework has been illustrated in the case of financial risk forecasting (see e.g., Harvey and Sucarrat (2014) for market risk, Oh and Patton (2013) for systematic risk, and Creal et al. (2014) for credit risk analysis), dependence modelling (see e.g., Harvey and Thiele (2015) and Janus et al. (2014)), and spatial econometrics (see e.g., Blasques et al. (2014d) and Catania and Billé (2016)). For a more complete overview of the work on GAS models, we refer the reader to the GAS community page at http://www.gasmodel.com/.

It is important to note that, even though the GAS framework has been developed by econometricians, it is flexible enough to be used in all fields in which the use of time-varying parameter models is relevant. The main difficulty in using GAS models is to derive the score and Hessian and implementing the Maximum Likelihood estimation of the resulting nonlinear models. The R package GAS answers these needs by proposing an integrated set of R functions to do time series analysis in the R statistical language (R Core Team 2016) under the GAS framework. The functionalities include: (i) estimation, (ii) prediction, (iii) simulation, (iv) backtesting, and (v) graphical representation of the results, implying that it is ready to use in real-life applications. The user interface uses the R programming language, which has the advantage of being free and open source. However, most of the underlying routines are principally written in C++ exploiting the armadillo library (Sanderson 2010) and the R packages Rcpp (Eddelbuettel and François 2011; Eddelbuettel et al. 2016a) and RcppArmadillo (Eddelbuettel and Sanderson 2014; Eddelbuettel et al. 2016b) to speed up the computations. Furthermore, since the package is written with the S4 methods, R users with basic programming knowledge will find common functions such as coef(), plot() and show() to extract and analyze their

<sup>&</sup>lt;sup>1</sup>A typical example is the class of (G)ARCH models in which the squared (demeaned) return is the driver of time–variation in the conditional variance, independently of the shape of the conditional distribution of the return. To see that this is counter–intuitive, consider the case of observing a 10% return when the conditional mean is 0% and the volatility is 3%. Under the assumption of a normal distribution, the 10% return is a strong signal of an increase in volatility, while under a fat–tailed Student–t distribution, the signal is weakened because of the higher probability that the extreme value is an observation from the tails.

results. We believe that this aspect is of primary importance since it dramatically increases the number of potential users. The R package **GAS** is available from the CRAN repository at <a href="https://cran.r-project.org/package=GAS">https://cran.r-project.org/package=GAS</a>. Other codes available for specific GAS models are available in the GAS community page at <a href="http://www.gasmodel.com/">http://www.gasmodel.com/</a>. For instance, the R package <a href="beta-t-EGARCH">beta-t-EGARCH</a> model of Harvey (2013) and its skewed version introduced by Harvey and Sucarrat (2014).

The outline of the paper is as follows: Section 2 reviews the GAS framework to define time–varying parameter models, referring to the seminal works of Creal *et al.* (2013) and Harvey (2013). Section 3 introduces the R package **GAS** and illustrates how to to simulate, estimate and make predictions. Section 4 presents a real–life application to financial data. Section 5 concludes.

# 2. The GAS framework to modeling time-varying parameters

One of the most appealing characteristics of the GAS framework is its applicability to define time–varying parameter models in a large variety of univariate and multivariate time series settings. We try to be as general as possible in reviewing the GAS framework, and report in Appendix A the detailed equations for the specific case of a conditionally Student–t distributed random variable. In this section, we first introduce the notation and present the GAS model when the parameter space is unrestricted. We then show how a mapping function can be used to model the time–variation in the parameters when the parameter space is restricted. The section concludes by summarizing the Maximum Likelihood approach for GAS model estimation.

## 2.1. Model specification

Let  $\mathbf{y}_t \in \Re^N$  be an N-dimensional random vector at time t with conditional distribution:

$$\mathbf{y}_t | \mathbf{y}_{1:t-1} \sim p(\mathbf{y}_t; \boldsymbol{\theta}_t) ,$$
 (1)

where  $\mathbf{y}_{1:t-1} \equiv (\mathbf{y}'_1, \dots, \mathbf{y}'_{t-1})'$  contains the past values of  $\mathbf{y}_t$  up to time t-1 and  $\boldsymbol{\theta}_t \in \Theta \subseteq \mathbb{R}^J$  is a vector of time-varying parameters which fully characterizes  $p(\cdot)$  and only depends on  $\mathbf{y}_{1:t-1}$  and a set of static additional parameters  $\boldsymbol{\xi}$ , i.e.,  $\boldsymbol{\theta}_t \equiv \boldsymbol{\theta}(\mathbf{y}_{1:t-1}, \boldsymbol{\xi})$  for all t. The main feature of GAS models is that the evolution in the time-varying parameter vector  $\boldsymbol{\theta}_t$  is driven by the score of the conditional distribution defined in (1), together with an autoregressive component:

$$\boldsymbol{\theta}_{t+1} \equiv \boldsymbol{\kappa} + \mathbf{A} \, \mathbf{s}_t + \mathbf{B} \, \boldsymbol{\theta}_t \,, \tag{2}$$

where,  $\kappa$ , **A** and **B** are matrices of coefficients with proper dimensions collected in  $\xi$ , and  $\mathbf{s}_t$  is a vector which is proportional to the score of (1):

$$\mathbf{s}_t \equiv \mathbf{S}_t(\boldsymbol{\theta}_t) \, \boldsymbol{\nabla}_t(\mathbf{y}_t, \boldsymbol{\theta}_t) \, .$$

The matrix  $\mathbf{S}_t$  is a  $J \times J$  positive definite scaling matrix known at time t and:

$$\boldsymbol{\nabla}_t(\mathbf{y}_t, \boldsymbol{\theta}_t) \equiv \frac{\partial \log p(\mathbf{y}_t; \boldsymbol{\theta}_t)}{\partial \boldsymbol{\theta}_t} \,,$$

is the score of (1) evaluated at  $\theta_t$ . Creal *et al.* (2013) suggest to set the scaling matrix  $\mathbf{S}_t$  to a power  $\gamma > 0$  of the inverse of the Information Matrix of  $\theta_t$  to account for the variance of  $\nabla_t$ . More precisely:

$$\mathbf{S}_t(\boldsymbol{\theta}_t) \equiv \mathcal{I}_t(\boldsymbol{\theta}_t)^{-\gamma}$$
,

with:

$$\mathcal{I}_{t}(\boldsymbol{\theta}_{t}) \equiv \mathsf{E}_{t-1} \left[ \boldsymbol{\nabla}_{t}(\mathbf{y}_{t}, \boldsymbol{\theta}_{t}) \boldsymbol{\nabla}_{t}(\mathbf{y}_{t}, \boldsymbol{\theta}_{t})' \right] , \tag{3}$$

where the expectation is taken with respect to the conditional distribution of  $\mathbf{y}_t$  given  $\mathbf{y}_{1:t-1}$ . The additional parameter  $\gamma$  is fixed by the user and usually takes value in the set  $\{0, \frac{1}{2}, 1\}$ . When  $\gamma = 0$ ,  $\mathbf{S}_t = \mathbf{I}$  and there is no scaling. If  $\gamma = 1$  ( $\gamma = \frac{1}{2}$ ), the conditional score  $\nabla_t(\mathbf{y}_t, \boldsymbol{\theta}_t)$  is premultiplied by the inverse of (the square root of) its covariance matrix  $\mathcal{I}_t(\boldsymbol{\theta}_t)$ .

It is worth noting that, whatever the choice of  $\gamma$ ,  $\mathbf{s}_t$  is a Martingale Difference (MD) with respect to the distribution of  $\mathbf{y}_t$  given  $\mathbf{y}_{1:t-1}$ , *i.e.*,  $\mathsf{E}_{t-1}[\mathbf{s}_t] = \mathbf{0}$  for all t. Furthermore, when  $\gamma = \frac{1}{2}$ , the additional moment condition  $\mathsf{V}_{t-1}[\mathbf{s}_t] = \mathbf{I}$  can be easily derived. Due to the fact that  $\mathbf{s}_t$  is a MD, if the spectral radius of  $\mathbf{B}$  is less then one<sup>3</sup>, the updating equation of  $\boldsymbol{\theta}_t$  reported in (2) implies a mean reverting process for  $\boldsymbol{\theta}_t$  through the long–term mean  $(\mathbf{I} - \mathbf{B})^{-1} \boldsymbol{\kappa}$ , which means that the unconditional value of  $\boldsymbol{\theta}_t$  is  $(\mathbf{I} - \mathbf{B})^{-1} \boldsymbol{\kappa}$ . It follows that, the J-valued vector  $\boldsymbol{\kappa}$  and the  $J \times J$  matrix  $\mathbf{B}$  control for the level and the persistence of the process, respectively.

The additional  $J \times J$  matrix of coefficients  $\mathbf{A}$ , that premultiplies the scaled score  $\mathbf{s}_t$ , controls for the impact of  $\mathbf{s}_t$  to  $\boldsymbol{\theta}_{t+1}$ . Specifically, as detailed in Creal *et al.* (2013), the quantity  $\mathbf{s}_t$  indicates the direction to update the vector of parameters from  $\boldsymbol{\theta}_t$ , to  $\boldsymbol{\theta}_{t+1}$ , acting as a steepest ascent algorithm for improving the model local fit given the current parameter position. Interestingly, this updating procedure resembles the well–known Newton–Raphson algorithm. Hence,  $\mathbf{A}$  can be interpreted as the step of the update, and needs to be designed in a way to do not distort the signal coming from  $\mathbf{s}_t$ ; see Section 2.3.

#### 2.2. Reparametrization

In (2) the parameter vector  $\boldsymbol{\theta}_t$  has a linear specification and is thus unbounded. In practice, the parameter space of  $\boldsymbol{\theta}_t$  is often restricted ( $\Theta \subset \Re^J$ ). For instance, when we model the scale parameter of a Student–t distribution, we need to ensure its positiveness. Even if this problem can be solved by imposing constraints on  $\boldsymbol{\xi}$  (as is done in the GARCH model, see, Bollerslev 1986), the standard solution under the GAS framework is to use a (possibly nonlinear) link function  $\Lambda(\cdot)$  that maps  $\tilde{\boldsymbol{\theta}}_t \in \Re^J$  into  $\boldsymbol{\theta}_t$  and where  $\tilde{\boldsymbol{\theta}}_t \in \Re^J$  has the linear dynamic specification of (2). Specifically, let  $\Lambda: \Re^J \to \Theta$  be a twice differentiable vector–valued mapping function such that  $\Lambda(\tilde{\boldsymbol{\theta}}_t) = \boldsymbol{\theta}_t$ . The updating equation for  $\boldsymbol{\theta}_t$  is then given by:

$$\begin{split} & \boldsymbol{\theta}_t \equiv \boldsymbol{\Lambda}(\widetilde{\boldsymbol{\theta}}_t) \\ & \widetilde{\boldsymbol{\theta}}_t \equiv \boldsymbol{\kappa} + \mathbf{A}\widetilde{\mathbf{s}}_t + \mathbf{B}\widetilde{\boldsymbol{\theta}}_{t-1} \,, \end{split} \tag{4}$$

where  $\widetilde{\mathbf{s}}_t \equiv \widetilde{\mathbf{S}}_t(\widetilde{\boldsymbol{\theta}}_t) \widetilde{\boldsymbol{\nabla}}_t(\mathbf{y}_t, \widetilde{\boldsymbol{\theta}}_t)$  and  $\widetilde{\boldsymbol{\nabla}}_t(\mathbf{y}_t, \widetilde{\boldsymbol{\theta}}_t)$  represents the score of (1) with respect to  $\widetilde{\boldsymbol{\theta}}_t$ , and, consequently,  $\widetilde{\mathbf{S}}_t(\widetilde{\boldsymbol{\theta}}_t)$  can depend on the information matrix of  $\widetilde{\boldsymbol{\theta}}_t$  given by  $\widetilde{\mathcal{I}}_t(\widetilde{\boldsymbol{\theta}}_t)$ . Denote the

<sup>&</sup>lt;sup>2</sup>We denote by **I** the identity matrix of appropriate size.

<sup>&</sup>lt;sup>3</sup>The spectral radius of a  $L \times L$  matrix **X** is defined as  $\tau(\mathbf{X}) \equiv \max(|\tau_1|, \dots, |\tau_L|)$ , where  $\tau_i$  is the *i*-th eigenvalue of **X**, for  $i = 1, \dots, L$ .

Jacobian matrix of  $\Lambda(\cdot)$  evaluated at  $\widetilde{\boldsymbol{\theta}}_t$  as follows:

$$\mathcal{J}(\widetilde{\boldsymbol{\theta}}_t) \equiv \frac{\partial \Lambda(\widetilde{\boldsymbol{\theta}}_t)}{\partial \widetilde{\boldsymbol{\theta}}_t} \ .$$

Then, the following relations hold:

$$\begin{split} \widetilde{\boldsymbol{\nabla}}_t(\mathbf{y}_t, \widetilde{\boldsymbol{\theta}}_t) &= \mathcal{J}(\widetilde{\boldsymbol{\theta}}_t)' \boldsymbol{\nabla}_t(\mathbf{y}_t, \boldsymbol{\theta}_t) \\ \widetilde{\mathcal{I}}_t(\widetilde{\boldsymbol{\theta}}_t) &= \mathcal{J}(\widetilde{\boldsymbol{\theta}}_t)' \mathcal{I}_t(\boldsymbol{\theta}_t) \mathcal{J}(\widetilde{\boldsymbol{\theta}}_t) \,. \end{split}$$

This way, almost all the nonlinear constraints can be easily handled via the definition of a proper mapping function  $\Lambda(\cdot)$  and its associated Jacobian matrix  $\mathcal{J}(\cdot)$ . The coefficients to be estimated are gathered into  $\boldsymbol{\xi} \equiv (\boldsymbol{\kappa}, \mathbf{A}, \mathbf{B})$  and estimated by numerically maximizing the (log-)likelihood function as detailed in Section 2.3.<sup>4</sup> In Appendix B we discuss the choice of mapping function for GAS models in more details.

#### 2.3. Maximum likelihood estimation

A useful property of GAS models is that, given the past information and the static parameter vector  $\boldsymbol{\xi}$ , the vector of time-varying parameters,  $\boldsymbol{\theta}_t$ , is perfectly predictable and the loglikelihood function can be easily evaluated via the prediction error decomposition. More precisely, for a sample of T realizations of  $\mathbf{y}_t$ , collected in  $\mathbf{y}_{1:T}$ , the vector of parameters  $\boldsymbol{\xi}$  can be estimated by Maximum Likelihood (ML) as the solution of:

$$\widehat{\boldsymbol{\xi}} \equiv \arg \max_{\boldsymbol{\xi}} \mathcal{L}(\boldsymbol{\xi}; \mathbf{y}_{1:T}), \qquad (5)$$

where:

$$\mathcal{L}\left(\boldsymbol{\xi}; \mathbf{y}_{1:T}\right) \equiv \log p\left(\mathbf{y}_{1}; \boldsymbol{\theta}_{1}\right) + \sum_{t=2}^{T} \log p\left(\mathbf{y}_{t}; \boldsymbol{\theta}_{t}\right) ,$$

 $\theta_1 \equiv (\mathbf{I} - \mathbf{B})^{-1} \kappa$ , and, for t > 1,  $\theta_t \equiv \theta(\mathbf{y}_{1:t-1}, \boldsymbol{\xi})$ . Note the dependence of  $\theta_t$  on  $\boldsymbol{\xi}$  and  $\mathbf{y}_{1:t-1}$ . There are two important caveats in the ML evaluation of GAS models. The first one is that, from a theoretical perspective, ML estimation of GAS models is an on-going research topic. General results are reported by Harvey (2013), Blasques *et al.* (2014a) and Blasques *et al.* (2014b), while results for specific models have been derived by Andres (2014) and Blasques *et al.* (2014d).

The second one is that, even when the ML estimator is consistent and asymptotically normal, the numerical maximization of the loglikelihood function in (5) can be challenging, because of the nonlinearities induced by  $\Lambda(\cdot)$  and the way  $\mathbf{y}_t$  enters the scaled score  $\mathbf{s}_t$ . Consequently, when the optimizer is gradient-based, good starting values need to be selected for GAS models. In the R package **GAS**, starting values for the optimizer are chosen in the following way: (i) estimate the static version of the model (*i.e.*, with  $\mathbf{A} = \mathbf{0}$  and  $\mathbf{B} = \mathbf{0}$ ) and set the initial value of  $\kappa$  accordingly, and (ii) perform a grid search for the coefficients contained in  $\mathbf{A}$  and  $\mathbf{B}$ . Further technical details are presented in Section 3.2.

<sup>&</sup>lt;sup>4</sup>Clearly, the coefficients  $\kappa$ , **A** and **B** in (4) are different from those of (2), however, for notational purposes, we continue to use the same notation.

Implementation of the models in the R package **GAS** follows the common approach in the GAS literature. First, matrices **A** and **B** are constrained to be diagonal. Second, in order to avoid an explosive pattern for  $\tilde{\boldsymbol{\theta}}_t$ , the spectral radius of **B** is constrained to be less than one. Third, the positiveness of each element of **A** is imposed in order to do not distort the signal coming from the conditional score  $\mathbf{s}_t$ .

# 3. The R package GAS

The R package GAS offers an integrated environment to deal with GAS models in R. Its structure is somehow similar to the R package rugarch (Ghalanos 2015b) for GARCH models, which is widely used by practitioners and academics. The similarities concern the steps the user has to do to perform her analysis as well as the type of functions she faces. Specifically, the first step is to specify the model, which means choosing: (i) the assumptions for the conditional distribution of the data, (ii) the set of parameters that have to vary over time and, (iii) the scaling mechanism for the conditional score. These steps are detailed in Section 3.1. Once the model is properly specified, the user can estimate the unknown parameters in  $\xi$  by numerical maximization of the log-likelihood function as detailed in Section 3.2. Finally, predictions according to the estimated model can be easily performed; see Section 3.3. Simulation of GAS models is presented in Section 3.4.

Functions for: (i) specification, (ii) estimation, (iii) forecasting and (iv) simulation are available for univariate and multivariate time series. The general nomenclature for the functions when we consider univariate time series is "UniGAS...()" and that for multivariate time series is "MultiGAS...()".

In the R package GAS, several datasets are also included for reproducibility purposes, such as: US inflation (cpichg), US unemployment rate (usunp), realized volatility of the S&P500 Index (sp500rv) and intraday bid and ask quotes for Citygroup corporation (tqdata). These datasets are freely available online; see the R documentation for references. In this section, we use the monthly US inflation measured as the logarithmic change in the CPI available from the Federal Reserve Bank of St. Louis website <a href="https://fred.stlouisfed.org/">https://fred.stlouisfed.org/</a>. This dataset can be easily loaded in the R workspace using: data("cpichg", package = "GAS").

## 3.1. Specification

Specification of GAS models is the first step the user needs to undertake. This is achieved by using the UniGASSpec() and MultiGASSpec() functions, in the cases of univariate and multivariate models, respectively. Both functions accept three arguments and return an object of the class uGASSpec and mGASSpec, respectively. The three arguments are:

- Dist: A character indicating the label of the conditional distribution assumed for the data. Available distributions can be displayed using the function DistInfo() and are reported in Table 1. By default Dist = "norm", i.e., the Gaussian distribution.
- ScalingType: A character indicating the scaling mechanism for the conditional score, i.e., the value of the  $\gamma$  parameter in (3). Possible choices are "Identity" ( $\gamma = 0$ ), "Inv" ( $\gamma = 1$ ) and "InvSqrt" ( $\gamma = \frac{1}{2}$ ). Note that, for some distributions only ScalingType = "Identity" is supported; see function DistInfo() and Table 1. By

Label	Name	Type	Parameters #		Scaling Type	
norm	Gaussian	univariate	location, scale	2	Identity, Inv, InvSqrt	
std	Student $-t$ (i)	univariate	location, scale, shape	3	Identity, Inv, InvSqrt	
sstd	Skew-Student-t (ii)	univariate	location, scale, skewness, shape		Identity	
ald	Asymmetric Laplace (iii)	univariate	location, scale, skewness	3	Identity, Inv, InvSqrt	
poi	Poisson (iv)	univariate	location	1	Identity, Inv, InvSqrt	
gamma	Gamma	univariate	scale, shape	2	Identity, Inv, InvSqrt	
exp	Exponential (v)	univariate	location	1	Identity, Inv, InvSqrt	
beta	Beta (vi)	univariate	scale, shape	2	Identity, Inv, InvSqrt	
mvnorm	Multivariate Gaussian	multivariate	location, scale, correlation	9 (vii)	Identity	
mvt	${\bf Multivariate~Student}{-}t$	$\operatorname{multivariate}$	location, scale, correlation, shape	relation, shape 10 (vii) Identity		

Table 1: Statistical distributions or which the R package **GAS** provides the functionality to simulate, estimate and forecast the time-variation in its parameters. The fifth column, #, reports the number of parameters of the distribution. Note: (i) the usual Student-t distribution (not reparametrised in terms of the variance parameter), (ii) the reparametrised Skew-Student-t such that the location and scale parameters coincide with the mean and the standard deviation of the distribution as done in the **rugarch** package, (iii) the **ald** distribution used the  $\theta$ ,  $\sigma$  and  $\kappa$  reparametrization, as specified in Kotz et al. (2001), (iv) for the Poisson distribution **location** means the usual intensity parameter, (v) for the Beta distribution shape means the usual  $\alpha$  parameter and scale means the usual  $\beta$  parameter, (vi) for the Exponential distribution **location** means the usual rate parameter, (vii) for N=3.

default ScalingType = "Identity", i.e., no scaling occurs.<sup>5</sup>

- GASPar: A named list with boolean entries containing information about which parameters of the conditional distribution have to be time-varying. Generally, each univariate distribution is identified by a series of maximum four parameters. These are indicated by location, scale, skewness and shape. Note that, for some distributions, these labels are not strictly related to their literal statistical meaning. Indeed, for the Exponential distribution exp, the term location indicates the usual intensity rate parameter; see the DistInfo() function for more details. For multivariate distributions, the set of parameters is indicated by location, scale, correlation and shape<sup>6</sup>. For example, in the case of a multivariate Student-t distribution with mean vector  $\mu_t$ , scale matrix  $\Sigma_t \equiv \mathbf{D}_t \mathbf{R}_t \mathbf{D}_t$ , where  $\mathbf{D}_t$  is the diagonal matrix of scales and  $\mathbf{R}_t$  is the correlation matrix, and  $\nu_t$  degrees of freedom, we have that: location refers to  $\mu_t$ , scale refers to  $\mathbf{D}_t$ , correlation refers to  $\mathbf{R}_t$  and shape refers to  $\nu_t$ . By default, GASPar = list(location = FALSE, scale = TRUE, skewness = FALSE, shape = FALSE) for the univariate case, and GASPar = list(location = FALSE, scale = TRUE, correlation = FALSE, shape = FALSE, shape = FALSE)

The function MultiGASSpec() also accepts the additional boolean argument ScalarParameters controlling for the parametrization of  $\mathbf{A}$  and  $\mathbf{B}$  in (4). Setting ScalarParameters = TRUE (the default value), the coefficients controlling the evolution of the location, scale and correlation parameters are constrained to be the same across each group. Specifically, if  $\mathbf{y}_t \in \Re^3$  follows a GAS process with conditional multivariate Gaussian distribution, the vector of time—

<sup>&</sup>lt;sup>5</sup>In the R package **GAS** the information matrices and the scores are always computed using their analytical formulations.

<sup>&</sup>lt;sup>6</sup>In the R documentation an extra parameter, shape2, is reported. This will be used for future extensions of the package.

varying parameters is  $\boldsymbol{\theta}_t = (\mu_{1,t}, \mu_{2,t}, \mu_{3,t}, \sigma_{1,t}, \sigma_{2,t}, \sigma_{3,t}, \rho_{21,t}, \rho_{31,t}, \rho_{32,t})'$ . If ScalarParameters = TRUE, the matrix of coefficients **A** is parameterized as:

$$\mathbf{A} \equiv \operatorname{diag}\left(a_{\mu}, a_{\mu}, a_{\mu}, a_{\sigma}, a_{\sigma}, a_{\sigma}, a_{\rho}, a_{\rho}, a_{\rho}\right) \,,$$

while, if ScalarParameters = FALSE, the matrix of coefficients A takes the form:

$$\mathbf{A} \equiv \operatorname{diag}\left(a_{\mu_1}, a_{\mu_2}, a_{\mu_3}, a_{\sigma_1}, a_{\sigma_2}, a_{\sigma_3}, a_{\rho_{21}}, a_{\rho_{31}}, a_{\rho_{32}}\right) \,.$$

Hence, in the latter case, each element of  $\boldsymbol{\theta}_t$  evolves heterogeneously with respect to the others. The same constraints are applied to  $\mathbf{B}$ , which means that, if ScalarParameters = TRUE, for the general N case, the number of parameters decreases from  $3N\left(N+1\right)/2$  to  $N\left(N+1\right)/2+2$ . Additional constraints are introduced through the GASPar argument as in the univariate case; see help("MultiGASSpec").

As an illustration, assume that we want to specify a Student–t GAS model with time–varying conditional mean and scale parameters, but fixed degree of freedom, i.e.,  $\nu_t = \nu$ . This can be easily done with the following lines of code:

Details about the object returned from UniGASSpec() are printed in the console by simply calling GASSpec:

R> GASSpec

Since the scaling matrix  $S_t$  is set to the identify matrix (i.e., ScalingType = "Identity") this model for the conditional Student—t distribution corresponds to the one described in Appendix A. Multivariate GAS specifications are analogously specified using the MultiGASSpec() function; see help("MultiGASSpec").

#### 3.2. Estimation

Similar to model specification, estimation is handled with two different functions for univariate and multivariate models: UniGASFit() and MultiGASFit(), respectively. These functions require only two arguments: the GAS specification object GASSpec and the data, and returns an object of the class uGASFit or mGASFit. As an example, let us estimate the GAS model previously specified using the US inflation data included in the R package GAS:

```
R> data("cpichg", package = "GAS")
R> Fit <- UniGASFit(GASSpec, cpichg)</pre>
```

The computational time is less than one second on a modern computer. The optimizer used is the General Nonlinear Augmented Lagrange Multiplier method of Ye (1988) available in the R package **Rsolnp** (Ghalanos and Theussl 2016). Results can be inspected by calling the object Fit.

Elapsed time: 0.01 mins

The output printed in the console is divided into: (i) the summary of the model, (ii) the estimated coefficients along with significance levels according to their asymptotic normal distribution, (iii) the unconditional level of the parameters, *i.e.*,  $\Lambda((\mathbf{I} - \hat{\mathbf{B}})^{-1}\hat{\boldsymbol{\kappa}})$ , (iv) AIC and BIC information criteria in addition to the number of estimated parameters (np), the log-likelihood (11k) evaluated at its optimum, and (v) the computation time.

Concerning the estimated coefficients, kappa1, kappa2 and kappa3 are the elements of vector  $\kappa$  in (9), i.e.,  $\kappa_{\mu}$ ,  $\kappa_{\phi}$  and  $\kappa_{\nu}$ , respectively. Analogously, a1 and a2 are the estimates of  $a_{\mu}$  and  $a_{\phi}$  and b1 and b2 are estimates of  $b_{\mu}$  and  $b_{\phi}$ , where  $\phi$  refers to the scale parameter of the Student-t distribution; see Appendix A. Note that, since we have specified scale = FALSE in the UniGASSpec() function, coefficients a3 and b3, corresponding to  $a_{\nu}$  and  $b_{\nu}$  are not reported (and constrained to zero during the optimization).

The R package **GAS** provides several methods to extract the relevant estimated quantities for objects of the class uGASFit or mGASFit. They allow us to: (i) calculate several quantities of the estimated conditional distribution at each point in time, such as: quantiles, conditional moments and filtered parameters (see quantile(Fit), getMoments(Fit) and getFilteredParameters(Fit), respectively), (ii) extract the estimated coefficients (coef(Fit)), (iii) generate a graphical representation of the results (plot(Fit)); see help("uGASFit") for details.

## 3.3. Forecasting

Forecasting is a crucial aspect in applied time series analysis. Given the parametric assumption of GAS models, predictions are usually given in the form of density forecasts, *i.e.*, the distribution of  $\mathbf{y}_{T+h}|\mathbf{y}_{1:T}$  for  $h \geq 1$ . Knowing the predictive density, practitioners can extract any relevant quantities such as future expected value  $\mathsf{E}_T[\mathbf{y}_{T+h}]$  or (co-)variance  $\mathsf{V}_T[\mathbf{y}_{T+h}]$ . For GAS models, the one-step ahead predictive distribution (h=1) is analytically available while it needs to be estimated by simulation in the multi-step ahead case (h>1).

The R package GAS can handle both one—step and multi—step ahead forecasts. Consistent with previous nomenclature, functions for univariate and multivariate predictions are UniGASFor() and MultiGASFor(), respectively. These functions accept an object of the class uGASFit or mGASFit, created using the functions UniGASFit() and MultiGASFit(), and return an object of the class uGASFor and mGASFor, respectively. Additional arguments are:

- H: a numeric integer value representing the forecast horizon, i.e., h. By default H = 1.
- B: a numeric integer value representing the number of draws to approximate the multistep ahead predictive distribution when h > 1. By default B = 1e4.
- ReturnDraws: a boolean controlling if the simulated draws from  $\mathbf{y}_{T+1}|\mathbf{y}_{1:T}, \mathbf{y}_{T+2}|\mathbf{y}_{1:T}, \dots, \mathbf{y}_{T+h}|\mathbf{y}_{1:T}$  have to be returned. By default ReturnDraws = FALSE.

Other arguments to perform rolling—type of forecasts are detailed in the documentation; see help("UniGASFor"). Practically, if we want to predict the next—year inflation (i.e., h = 12 with the monthly series cpichg), after having estimated the GAS model of Section 3.2, we can execute the following code:

```
R> Forecast <- UniGASFor(Fit, H = 12)</pre>
```

and inspect the results by calling the object Forecast:

#### R> Forecast

```
- Univariate GAS Forecast -
```

Model Specification

Conditional distribution: std Score scaling type: Identity

Horizon: 12

Rolling forecast: FALSE

-----

#### Parameters forecast:

```

T+11 0.07557 0.5199 6.526

T+12 0.07507 0.5465 6.526

which returns some model information and the predictions of future model parameters based on averages over B draws. Forecast is an object of the class uGASFor and comes with several methods to extract and visualize the results; see help("uGASFor").

As commonly done in time series analysis, predictions are generated from models fitted to rolling windows. The R package **GAS** includes this functionality via UniGASRoll() and MultiGASRoll(). These functions accept several arguments that we briefly describe in the univariate case:

- data: a vector of length T+ForecastLength containing all the observations.
- GASSpec: an object of the class uGASSpec created with UniGASSpec().
- ForecastLength: a numeric integer which specifies the length of the out-of-sample.
- RefitEvery: a numeric integer of periods before coefficients are re-estimated.

RefitWindow: a character for the type of the window. As in the R package rugarch, we define the options: RefitWindow = "recursive" and RefitWindow = "moving".
 If RefitWindow = "recursive" all past observations are used when the model is reestimated. If RefitWindow = "moving" initial observations are eliminated.

Other arguments useful to tailor the forecasting procedure and to parallelize the code execution are available and detailed in the R documentation; see help("UniGASRoll").

Suppose now we are interested in assessing the forecast performance of the GAS model with a Student–t conditional distribution and time–varying location and scale parameters, detailed in Appendix A, and specified in the object GASSpec in Section 3.1. We treat the last 150 observations of cpichg as out–of–sample and run a rolling–window forecast exercise using the following portion of code:

where model coefficients are re—estimated quarterly (*i.e.*, every three observations with monthly data) using a moving windows (RefitWindow = "moving"). The code automatically makes a series of one—step ahead rolling predictions according to the model estimated using only the past information. This way, the user can perform out—of—sample analysis with GAS models. The object Roll belongs to the class uGASRoll which, as uGASFit and uGASFor, comes with several methods to extract and represent the results; see help("uGASRoll").

## 3.4. Simulation

Simulation of univariate and multivariate GAS models is straightforward with the R package GAS. This can be easily done via UniGASSim() and MultiGASSim(); see the R documentation. Several examples, also investigating the finite sample properties of the ML estimator for GAS models, are reported in the inst/test/Simulation.R file included in the package tarball.

Besides selecting the conditional distribution of the time series process, the user of course needs to specify also the static parameters  $\boldsymbol{\xi}$  governing the dynamics in  $\boldsymbol{\theta}_t$ . More precisely, for simulation of GAS models, the vector  $\boldsymbol{\kappa}$  and the matrices  $\mathbf{A}$  and  $\mathbf{B}$ , need to be specified. It is worth stressing that, the definition of  $\boldsymbol{\kappa}$  can be tricky, especially for multivariate models. The difficulty emerges from the fact that,  $\boldsymbol{\kappa}$  determines the unconditional value of the reparametrised vector of parameters  $\boldsymbol{\theta}_t$ , implying that, if the user wants to specify the model in terms of a target value  $\boldsymbol{\theta}^*$  she needs to know the inverse of the mapping function  $\boldsymbol{\Lambda}(\cdot)$ . To address this problem, the functions UniUnmapParameters() and MultiUnmapParameters(), representing  $\boldsymbol{\Lambda}^{-1}(\cdot)$ , are available for univariate and multivariate models, respectively. This way, the user can easily specify  $\boldsymbol{\kappa}$  such that  $\boldsymbol{\kappa}^* \equiv (\mathbf{I} - \mathbf{B})\boldsymbol{\Lambda}^{-1}(\boldsymbol{\theta}^*)$ . Table 2 lists the numerical bounds imposed for the univariate distributions, such that UniUnmapParameters() cannot takes values outside those ranges. For the multivariate case, please refer to the examples reported in the inst/test/SimulateGAS.R file included in the package tarball.

<sup>&</sup>lt;sup>7</sup>Here we define the "target value" as the unconditional level of the parameters the user has in mind. This targeting approach requires the time–varying parameter model to be stationary, as explained in, *e.g.*, Blasques *et al.* (2014c).

Label	location	scale	skewness	shape
norm	$\Re$	$\Re^+$	_	-
std	$\Re$	$\Re^+$	_	(2.01, 50.0)
snorm	$\Re$	$\Re^+$	(0.1, 2.0)	_
sstd	$\Re$	$\Re^+$	(0.1, 2.0)	(2.01, 50.0)
ald	$\Re$	$\Re^+$	$\Re^+$	_
poi	$\Re^+$	_	_	_
gamma	$\Re^+$	$\Re^+$	_	_
exp	$\Re^+$		_	_
beta	$\Re^+$	$\Re^+$	_	_

Table 2: Overview of the restrictions on the allowed values for the parameters of the univariate distributions, for which the R package **GAS** provides the functionality to simulate, estimate and forecast the time variation in the parameters. When the parameter space is  $\Re^+$ , we use the exponential link function reported in (10) with c = 0, while when the space is of the type (a, b), we use the modified logistic link function reported in (11); see Appendix B.

Suppose we want to simulate T=1,000 observations from the Student–t GAS model reported in Appendix A with time–varying location and scale, but constant shape parameters. Assume our target value for the parameters is  $\boldsymbol{\theta}^* = (\mu^*, \sigma^*, \nu^*)'$  with  $\mu^* = 0.1, \sigma^* = 1.5$  and  $\nu^* = 7$ . The matrix **A** and **B** are defined as:

$$\begin{split} \mathbf{A} &= \mathrm{diag} \left( 0.1, 0.4, 0.0 \right) \\ \mathbf{B} &= \mathrm{diag} \left( 0.9, 0.95, 0.0 \right), \end{split}$$

such that both the conditional mean and the conditional variance evolve quite persistently over time, while the shape parameter is constant. The implementation of UniUnmapParameters() and UniGASSim() proceeds as:

```
A \leftarrow diag(c(0.1, 0.4, 0.0))

B \leftarrow diag(c(0.9, 0.95, 0.0))

ThetaStar \leftarrow c(0.1, 1.5, 7.0)

Kappa \leftarrow (diag(3) - B) %*% UniUnmapParameters(ThetaStar, "std")

Sim \leftarrow UniGASSim(T = 1000, Kappa, A, B, Dist = "std", ScalingType = "Identity")
```

where Sim is an object of the class uGASSim and comes with several method such as show, plot, and getMoments, among others; see help("uGASSim").

# 4. Applications to financial data

In order to illustrate how the R package **GAS** can be used in practical situations, we present an empirical application with univariate and multivariate time series of financial returns. We consider daily log-returns (in percentage points) of the Dow Jones 30 constituents available in the dji30ret dataset. This dataset includes the closing value log-returns from March 3rd,

1987 to February 3rd, 2009 for a total of 5,521 observations per series. The dataset can be easily loaded in the workspace using:

```
R> library("GAS")
R> data("dji30ret", package = "GAS")
```

where dji30ret is a  $5521 \times 30$  data.frame containing the daily log-returns. Our analysis is a typical out-of-sample exercise, meaning that: (i) we estimate the models using an insample period, (ii) we do predictions of the conditional distribution for the observations in the out-of-sample period, (iii) and that we compare the models according to their out-of-sample performance.

The models we consider are univariate/multivariate GAS models estimated with the R package GAS, and univariate/multivariate GARCH models estimated using the popular R packages rugarch (Ghalanos 2015b) and rmgarch (Ghalanos 2015a), respectively. The univariate specifications we consider are: (i) the Skew-Student-t GAS model with only time-varying scale parameter (i.e., Dist = "sstd") and, (ii) the GARCH(1,1) model with Skew-Student-t distributed error. For both models we employ the Skew-Student-t distribution of Fernández and Steel (1998) reparametrised such that the location and scale parameters coincide with the mean and the standard deviation of the distribution as done in the rugarch package.

For the multivariate specifications, we consider: (i) the GAS model with conditional multivariate Student–t distribution with time–varying scales and correlations used in Creal et al. (2011) and, (ii) the Dynamic Conditional Correlation (DCC) model of Engle (2002) with a conditional multivariate Student–t distribution. For simplicity, the multivariate analysis only considers three series of the whole dataset: Caterpillar Inc. (CAT), 3M (MMM) and Pfizer Inc. (PFE).

The code used to specify the univariate and multivariate GAS models is:

respectively.

The last H=3,000 observations (from January 27th, 1991, to the end of the sample) compose the out-of-sample period. During the out-of-sample period, one-step ahead density predictions are constructed by the univariate and multivariate models. Models (and therefore coefficients) are re-estimated using a moving-window every hundredth observations, as detailed in Section 3.3. One-step ahead rolling prediction are then computed as:

```
luGASRoll <- list()</pre>
```

for the univariate and multivariate cases, respectively.

Let us now compare the ability of GAS and GARCH models in predicting the one–step ahead distribution using so–called scoring rules, which compare the predicted density with the ex–post realized value of the return and deliver a score which defines a ranking across the alternative models at each point in time (Gneiting et al. 2007). Generally, we define  $S_{t+1} \equiv S(y_{t+1}, p(y_{t+1}; \hat{\theta}_{t+1}))$  as the score at time t+1 for having predicted  $p(y_{t+1}; \hat{\theta}_{t+1})$  when  $y_{t+1}$  has been realized. We consider two widely used scoring rules:

• The average weighted Continuous Ranked Probability Score (wCRPS):

$$\overline{wCRPS} \equiv \frac{1}{H} \sum_{t=T}^{T+H-1} \int_{-\infty}^{\infty} w(z) \left( F\left(z; \widehat{\boldsymbol{\theta}}_{t+1}\right) - \mathbb{I}_{\{y_{t+1} < z\}} \right)^2 dz, \tag{6}$$

where w(z) is a weight function that emphasizes regions of interest of the predictive distribution, such as the tails or the center. Similarly to Gneiting and Ranjan (2011), we consider the cases of: (i) a weighting that gives equal emphasis to all the parts of the distribution; w(z) = 1, (ii) a weighting that focuses on the center;  $w(z) = \phi_{a,b}(z)$ ; (iii) a weighting that focuses on the tails;  $w(z) = 1 - \phi_{a,b}(z)/\phi_{a,b}(0)$ , (iv) a weighting that focuses on the right tail;  $w(z) = \Phi_{a,b}(z)$ , and (v) a weighting that focuses on the left tail  $w(z) = 1 - \Phi_{a,b}(z)$ . The functions  $\phi_{a,b}(z)$  and  $\Phi_{a,b}(z)$  are the pdf and cdf of a Gaussian distribution with mean a and standard deviation b, respectively. The label uniform represents the case where equal emphasis is given to all the parts of the distribution.

• The average Negative Log Score (NLS):

$$\overline{NLS} \equiv -\frac{1}{H} \sum_{t=T}^{T+H-1} \log p(y_{t+1}; \widehat{\boldsymbol{\theta}}_{t+1}). \tag{7}$$

Consistent with Gneiting et al. (2007), we specify the Negative Log Score such that the "direction" between the two scoring rules is the same, i.e., forecasts with lower  $\overline{NLS}$  and lower  $\overline{wCRPS}$  are preferred.

The two aforementioned scoring rules can be easily evaluated using the BacktestDensity() function available in the R package GAS. The BacktestDensity() function accepts an object of the class uGASRoll, and returns a list with two elements: (i) the averages negative LS and wCRPS as in (7) and (6), and (ii) their values at each point in time. Additional arguments are:

- lower: numeric representing the lower bound used to approximate (6) by Monte Carlo integration as detailed in Gneiting and Ranjan (2011).
- upper: numeric as lower but for the upper bound.
- K: numeric integer representing the number of points used to discretize the integral in (6). By default K = 1000,

plus the two numeric arguments, a and b, representing a and b in the weight functions, by default a = 0.0 and b = 1.0.

In our case, in order to evaluate  $\overline{NLS}$  and  $\overline{wCRPS}$  for the first asset we can simply run:

R> DensityBacktest\$average

```
LS uniform center tails tail_r tail_1 -2.389e+00 1.329e-02 5.300e-03 7.310e-06 6.645e-03 6.648e-03
```

```
where lower = -1.0 and upper = 1.0.
```

Table 3 reports the test statistics for the Diebold and Mariano (1995) (DM) test of equal performance between the series of Negative Log Scores and weighed Continuous Ranked Probability Scores for univariate GAS and GARCH models across the out–of–sample period. Negative values indicate that GAS models generate more accurate predictions of the one–step ahead conditional distribution while positive values favour GARCH. We found that, for almost all the series, GAS outperforms GARCH at very high confidence levels according to both NLS and wCRPS. Interestingly, our results suggest that GAS delivers more accurate results whatever part of the conditional distribution the  $\overline{wCRPS}$  emphasizes.

For the multivariate analysis we only consider  $\overline{NLS}$ . In this case, the DM test statistic is -4.15, which strongly favours the GAS model against the DCC specification. To further

<sup>&</sup>lt;sup>8</sup>The two arguments lower and upper coincide with  $y_l$  and  $y_u$  in Equation 16 of Gneiting and Ranjan (2011), respectively. These are two numeric objects with no default value, *i.e.*, the user have to define these values according to her research design.

<sup>&</sup>lt;sup>9</sup>Equals to *I* in Equation 16 of Gneiting and Ranjan (2011).

<sup>&</sup>lt;sup>10</sup>These values can be chosen in order to target some "optimal" prediction level, or to add more flexibility and focus on specific parts the predictive distribution; see Gneiting and Ranjan (2011).

<sup>&</sup>lt;sup>11</sup>Chosen lower and upper values define a proper range for log–returns not in percentage points as the one considered here.

Table 3: Test statistics for the Diebold and Mariano (1995) test of equal performance between the series of negative Log Scores and weighed Continuous Ranked Probability Scores for univariate GAS and GARCH models across the out–of–sample logarithmic returns of Dow Jones 30 constituents. Negative values indicate that GAS models report more accurate predictions of the one–step ahead conditional distribution while positive values favour GARCH. The apexes a,b and c represent rejection of the null hypothesis of Equal Predictive Ability at the 1%,5% and 10% confidence levels, respectively. The out–of–sample period spans from January 27th, 1991, to February 3rd, 2009 for a total of 3,000 observations.

investigate this result, we report in Figure 1 the Cumulative sum of the differences between

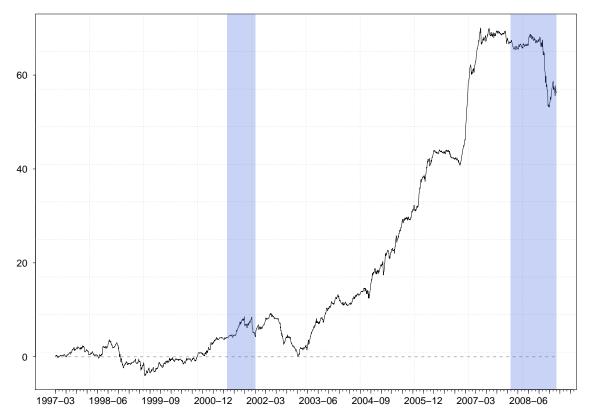

Figure 1: Cumulative out—of—sample Log Score differences between the multivariate Student—t GAS and the DCC(1,1) model of Engle (2002) with multivariate Student—t errors. Periods when the plot line slopes upward represent periods in which GAS outperforms GARCH, while downward—sloping segments indicate periods when the GARCH forecast is more accurate. The blue shaded area represents periods of recession in the US economy according to the "USREC" series available from the Federal Reserve Bank of St. Louis web site at https://fred.stlouisfed.org/series/USREC.

the Log Scores (CLS) of GAS and DCC defined as:

$$CLS_{T:T+l}^{GAS|DCC} \equiv \sum_{t=T}^{t=T+l-1} \log p\left(\mathbf{y}_{t+1}; \widehat{\boldsymbol{\theta}}_{t+1}^{GAS}\right) - \log p\left(\mathbf{y}_{t+1}; \widehat{\boldsymbol{\theta}}_{t+1}^{DCC}\right) \,,$$

where  $p\left(\mathbf{y}_{t+1}; \widehat{\boldsymbol{\theta}}_{t+1}^{GAS}\right)$  and  $p\left(\mathbf{y}_{t+1}; \widehat{\boldsymbol{\theta}}_{t+1}^{DCC}\right)$  are the densities predicted from GAS and DCC evaluated in  $\mathbf{y}_{t+1}$ , respectively. The series of Log Scores for the multivariate GAS models is available in the output of the BacktestDensity() function, or can be extracted using the LogScore method defined for mGASRoll objects:

## R> LS\_MGAS <- LogScore(mGASRoll)</pre>

Looking at Figure 1, periods when the plot line slopes upward represent periods in which GAS outperforms DCC, while downward–sloping segments indicate periods when the DCC forecast is more accurate. From this plot, we clearly understand the output of the DM test. Interestingly, we found that GAS starts dominating DCC after 2000.

## 5. Conclusion

This article introduced the R package **GAS** for simulating, estimating and forecasting time—varying parameter models under the Generalized Autoregressive Score framework. It allows practitioners in many scientific areas to perform their applied research using GAS models in a user—friendly environment.

We introduced the model specification in a general way and illustrated the package usage. In particular, we performed an empirical application using financial data in which we compared the performance of univariate and multivariate GAS and GARCH models. Given the flexibility of GAS models and the availability of several statistical distributions in the **GAS** package, a number of different applications can be easily handled, such as: (i) the analysis of integer valued time series using the Poisson GAS model (poi), (ii) the analysis of (0,1)—bounded time series using the Beta GAS model (beta), (iii) the analysis of strictly positive time series with an inverse location/scale dependence using the Gamma GAS model (gamma).

Finally, if you use R or GAS, please cite the software in publications.

# Computational details

The results in this paper were obtained using R 3.2.3 (R Core Team 2016) with the packages: GAS version 0.1.4 (Catania et al. 2016), MASS version 7.3-45 and (Venables and Ripley 2002; Ripley 2015), Rcpp version 0.12.7 (Eddelbuettel and François 2011; Eddelbuettel et al. 2016a), RcppArmadillo version 0.7.400.2.0 (Eddelbuettel and Sanderson 2014; Eddelbuettel et al. 2016b), Rsolnp version 1.16 (Ghalanos and Theussl 2016), xts version 0.9-7 (Ryan and Ulrich 2015) and quantmod version 0.4-6 (Ryan 2015). R itself and all packages used are available from CRAN at http://CRAN.R-project.org/. The package GAS is available from the CRAN repository at https://cran.r-project.org/package=GAS. The version under development is available in GitHub at https://github.com/LeopoldoCatania/GAS. Computations were performed on a Genuine Intel® quad core CPU i7-3630QM 2.40Ghz processor. Code outputs were obtained using options(digits = 4, max.print = 40, prompt = "R>")

The folder inst/doc inside the **GAS** package tarball contains additional technical documentations. A step by step guide on how to add a new statistical distribution in the **GAS** package is reported in the file AddNewDistribution.pdf.

## A. The GAS model with conditional Student-t distribution

Let us consider the case where the distribution of the univariate random variable  $y_t \in \Re$ , conditionally on  $\mathbf{y}_{1:t-1}$ , is Student-t with location  $\mu_t$ , scale  $\phi_t$  and  $\nu_t$  degrees of freedom, i.e.,  $\boldsymbol{\theta}_t = (\mu_t, \phi_t, \nu_t)'$  and:

$$p(y_t; \boldsymbol{\theta}_t) \equiv \frac{\Gamma\left(\frac{\nu_t + 1}{2}\right)}{\Gamma\left(\frac{\nu_t}{2}\right) \phi_t \sqrt{\pi \nu_t}} \left(1 + \frac{(y_t - \mu_t)^2}{\nu_t \phi_t^2}\right)^{-\frac{\nu_t + 1}{2}}.$$
 (8)

As will become clear, the score corresponding to the Student–t distribution has the advantage of dampening the effect of extreme observations on the future volatility, when the Student–t has sufficiently fat tails. It has been used by Creal  $et\ al.\ (2013)$  and Lucas and Zhang (2016) under the name tGAS, and by Harvey (2013) and Harvey and Luati (2014) under the name Beta–t–EGARCH.

Differentiating the logarithm of (8) with respect to  $\boldsymbol{\theta}_t$  leads to the score vector  $\boldsymbol{\nabla}_t(y_t, \boldsymbol{\theta}_t) = (\nabla_t^{\mu}, \nabla_t^{\phi}, \nabla_t^{\nu})'$ , with:

$$\begin{split} \nabla_t^{\mu} &\equiv \frac{(\nu_t + 1)(y_t - \mu_t)}{\nu_t \phi_t \left( 1 + \frac{(y_t - \mu_t)^2}{\nu_t \phi_t} \right)} \\ \nabla_t^{\phi} &\equiv \frac{(\nu_t + 1)(y_t - \mu_t)^2}{2\nu_t \phi_t^2 \left( 1 + \frac{(y_t - \mu_t)^2}{\nu_t \phi_t} \right)} - \frac{1}{\phi_t} \\ \nabla_t^{\nu} &\equiv \frac{1}{2} \psi \left( \frac{\nu_t + 1}{2} \right) - \frac{1}{2} \psi \left( \frac{\nu_t}{2} \right) - \frac{1}{2\nu_t} \\ &- \frac{1}{2} \log \left( 1 + \frac{(y_t - \mu_t)^2}{\nu_t \phi_t} \right) + \frac{(\nu_t + 1)(y_t - \mu_t)^2}{2\nu_t^2 \phi_t \left( 1 + \frac{(y_t - \mu_t)^2}{\nu_t \phi_t} \right)} \,, \end{split}$$

where  $\psi(\cdot)$  is the Digamma function. Without loss of generality, let us consider the case where  $\gamma=0$  with no reparametrization, i.e.,  $\theta_t=\widetilde{\theta}_t$ . The results when  $\gamma\neq 0$  and a mapping function  $\Lambda(\cdot)$  for  $\theta_t$  is introduced are qualitatively the same. Clearly, what controls for the response to extreme observations in the conditional score  $\nabla_t(y_t,\theta_t)$  is the degree of freedom parameter  $\nu_t$ . When  $\nu_t$  is small, say  $\nu_t=3$ , the conditional distribution of  $y_t$  has high probability mass in the tails, which means that extreme observations, which would be considered outliers under the conditionally normal distribution, are likely to be observed.

If we introduce the following mapping function for the unrestricted vector of parameter  $\widetilde{\boldsymbol{\theta}}_t = (\widetilde{\mu}_t, \widetilde{\phi}_t, \widetilde{\nu}_t)'$ :

$$\Lambda(\widetilde{\boldsymbol{\theta}}_t) \equiv \begin{cases} \mu_t \equiv \ \widetilde{\mu}_t \\ \phi_t \equiv \ \exp(\widetilde{\phi}_t) \\ \nu_t \equiv \ \exp(\widetilde{\nu}_t) + c \end{cases}$$

with c=2 in order to ensure the existence of  $V_{t-1}[y_t]$ , then the GAS updating step for  $\theta_t$  when  $\gamma=0$  takes the form:

$$\theta_{t+1} \equiv \Lambda(\widetilde{\boldsymbol{\theta}}_{t+1}) 
\widetilde{\boldsymbol{\theta}}_{t+1} \equiv \kappa + \mathbf{A} \mathcal{J}(\widetilde{\boldsymbol{\theta}}_{t})' \nabla_{t}(y_{t}, \boldsymbol{\theta}_{t}) + \mathbf{B} \widetilde{\boldsymbol{\theta}}_{t},$$
(9)

where  $\kappa \equiv (\kappa_{\mu}, \kappa_{\phi}, \kappa_{\nu})'$ ,  $\mathbf{A} \equiv \operatorname{diag}(a_{\mu}, a_{\phi}, a_{\nu})$  and  $\mathbf{B} \equiv \operatorname{diag}(b_{\mu}, b_{\phi}, b_{\nu})$ . In this particular case, the Jacobian matrix  $\mathcal{J}(\widetilde{\boldsymbol{\theta}}_t)$  takes the form:

$$\mathcal{J}(\widetilde{\boldsymbol{\theta}}_t) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \exp(\widetilde{\phi}_t) & 0 \\ 0 & 0 & \exp(\widetilde{\nu}_t) \end{pmatrix}.$$

Constraints on the evolution of the GAS parameters can be easily considered by fixing the values of the **A** and **B** elements. For example, if the constraint  $\nu_t = \nu$  has to be imposed, we set  $a_{\nu} = b_{\nu} = 0$  during the (log-)likelihood maximization.

# B. Mapping functions

Now we briefly discuss the choice of the mapping function  $\Lambda(\cdot)$  for GAS models. We indicate the *i*-th element of  $\boldsymbol{\theta}_t$  and  $\widetilde{\boldsymbol{\theta}}_t$  as  $\theta_{i,t}$  and  $\widetilde{\boldsymbol{\theta}}_{i,t}$ , respectively. Analogously, we refer to the *i*-th element of the vector-valued mapping function  $\Lambda(\cdot)$  as  $\lambda_i(\cdot)$ , such that  $\lambda_i(\widetilde{\boldsymbol{\theta}}_{i,t}) = \theta_{i,t}$ .

Generally, there are three types of constraints we want to impose on  $\theta_{i,t}$ :

- 1)  $\theta_{i,t} > c$ ,  $c \in \Re$
- 2)  $\theta_{i,t} \in (a,b)$ , for  $a,b \in \Re$  and b > a
- 3)  $\theta_{i,t} \in (a,b) | \boldsymbol{\theta}_t \in \Theta \text{ for } a,b \in \Re \text{ and } b > a$ ,

the additional case when  $\theta_{i,t} \in \Re$ , and thus  $\widetilde{\theta}_{i,t} = \theta_{i,t}$ , implicitly requires that  $\lambda_i : \Re \to \Re$  is the identity function.

The first case,  $\theta_{i,t} > c$ , <sup>12</sup> covers the situation where, for example,  $\theta_{i,t}$  is a scale parameter and, consequently, its positiveness has to be imposed (*i.e.*, c = 0). In this case,  $\lambda_i : \Re \to [c, \infty)$ , and the exponential link function, defined as:

$$\theta_{i,t} = \exp(\widetilde{\theta}_{i,t}) + c\,, (10)$$

can be employed. The second case,  $\theta_{i,t} \in (a,b)$ , covers the situation where, for example,  $p(\cdot; \boldsymbol{\theta}_t)$ , is the asymmetric Student–t distribution of Zhu and Galbraith (2010), and  $\theta_{i,t}$  is its skew parameter defined in (0,1). In the more general case we have  $\lambda_i : \Re \to (a,b)$ , and thus, the modified logistic function:

$$\theta_{i,t} = a + \frac{b - a}{1 + \exp(-\widetilde{\theta}_t)}, \tag{11}$$

can be employed. The last case,  $\theta_{i,t} \in (a,b) | \boldsymbol{\theta}_t \in \Theta$ , is more complicated and covers the situation where, for example,  $p(\cdot; \boldsymbol{\theta}_t)$  is a multivariate Gaussian distribution and  $\theta_{i,t}$  is one element of its correlation matrix  $\mathbf{R}_t$ . Clearly, in this case  $\theta_{i,t} \subseteq [-1,1]$ , with the equivalence corresponding to the case N=2. For the more general case N>1, we need to ensure that  $\mathbf{R}_t$  is positive definite, i.e.,  $\mathbf{x}'\mathbf{R}_t\mathbf{x}>0, \forall \mathbf{x}\in \Re^N$ . Following Creal et al. (2011), we employ the hyperspherical coordinates transformation originally proposed by Pinheiro and

<sup>&</sup>lt;sup>12</sup>The case  $\theta_{i,t} < c$  follows immediately.

Bates (1996) and subsequently discussed in Jaeckel and Rebonato (1999), Rapisarda et al. (2007) and Pourahmadi and Wang (2015). We define the general (h,k)-th lower diagonal element of  $\mathbf{R}_t$  as  $\rho_{hk,t} = \theta_{i,t}$  for h > k, h < N and  $\widetilde{\rho}_{hk,t} = \theta_{i,t}$ , for  $i = 1, \ldots, N(N-1)/2$ . Pourahmadi and Wang (2015) show that:

$$\rho_{hk,t} = c_{h1,t}c_{k1,t} + \sum_{m=2}^{h-1} c_{hm,t}c_{km,t} \prod_{l=1}^{m-1} s_{hl,t}s_{kl,t} + c_{hk,t} \prod_{l=1}^{h-1} s_{hl,t}s_{kl,1} \quad 1 \leq h < k \leq N \,,$$

where  $c_{hk,t} \equiv \cos\left(\widetilde{\rho}_{hk,t}\right)$  and  $s_{hk,t} \equiv \sin\left(\widetilde{\rho}_{hk,t}\right)$  for all  $1 \leq h < k \leq N$  ensure that  $\mathbf{R}_t \equiv \sum_{k=0}^{N} c_{kk,t} = \sum_{k=0}^{N} c_{kk,t}$  $\{\rho_{ij,t}\}_{i,j=1}^{N}$  is a proper correlation matrix.

These three specifications for  $\lambda_i(\cdot)$  cover all the cases considered in this article and in the R package GAS. Additional information are reported in the R documentation. Fore details on  $\Lambda\left(\cdot\right) \ \mathrm{and} \ \Lambda^{-1}\left(\cdot\right); \ \mathrm{see} \ \mathtt{help}( t^{"} ext{UniMapParameters"}) \ \mathrm{and} \ \mathtt{help}( t^{"} ext{UniUnmapParameters"}) \ \mathrm{in} \ \mathrm{the}$ univariate case and help("MultiMapParameters") and help("MultiUnmapParameters") in the multivariate case.
